Ophthalmologic Techniques for Evaluating Glaucoma

Description

Several techniques have been developed to measure the thickness of the optic nerve/retinal nerve fiber layer (RNFL) as a method to diagnose and monitor glaucoma. Measurement of ocular blood flow is also being evaluated as a diagnostic and management tool for glaucoma.

Background

Glaucoma is a disease characterized by degeneration of the optic nerve (optic disc). Elevated intraocular pressure has long been thought to be the primary etiology, but the relationship between intraocular pressure and optic nerve damage varies among patients, suggesting a multifactorial origin. For example, some patients with clearly elevated intraocular pressure will show no optic nerve damage, while other patients with marginal or no pressure elevation will, nonetheless, show optic nerve damage. The association between glaucoma and other vascular disorders such as diabetes or hypertension suggests vascular factors may play a role in glaucoma. Specifically, it has been hypothesized that reductions in blood flow to the optic nerve may contribute to the visual field defects associated with glaucoma.

A comprehensive ophthalmologic exam is required for the diagnosis of glaucoma, but no single test is adequate for establishing the diagnosis. A comprehensive ophthalmologic examination includes an examination of the optic nerve by fundoscopy, evaluation of visual fields, and measurement of ocular pressure. The presence of characteristic changes in the optic nerve or abnormalities in visual field, together with increased intraocular pressure, is sufficient for a definitive diagnosis. However, some patients will show ophthalmologic evidence of glaucoma with normal intraocular pressures, therefore an elevated intraocular pressure is not essential for diagnosis.

Conventional management of the patient with glaucoma principally involves drug therapy, to control elevated intraocular pressures, and serial evaluation of the optic nerve to follow disease progression. Standard methods of evaluation include careful direct examination of the optic nerve using ophthalmoscopy or stereophotography, or evaluation of visual fields. There has been interest in developing more objective, reproducible techniques both to document optic nerve damage and to detect early changes in the optic nerve and retinal nerve fiber layer (RNFL) before the development of permanent visual field deficits. Specifically, evaluating changes in the thickness of the RNFL has been investigated as a technique to diagnose and monitor glaucoma. In addition, there has been interest in
measuring ocular blood flow as a diagnostic and management tool for glaucoma. A variety of new techniques have been developed, as described here:

1. Techniques to Evaluate the Optic Nerve/Retinal Nerve Fiber Layer (Note: This policy only addresses uses of these techniques related to glaucoma.)
   a. **Confocal Scanning Laser Ophthalmoscopy:** Confocal scanning laser ophthalmoscopy (CSLO) is a laser-based image acquisition technique, which is intended to improve the quality of the examination compared to standard ophthalmologic examination. A laser is scanned across the retina along with a detector system. Only a single spot on the retina is illuminated at any time, resulting in a high-contrast image of great reproducibility that can be used to estimate the thickness of the RNFL. In addition, this technique does not require maximal mydriasis, which may be a problem in patients with glaucoma. The Heidelberg Retinal Tomography is probably the most common example of this technology.
   b. **Scanning Laser Polarimetry:** The RNFL is birefringent, causing a change in the state of polarization of a laser beam as it passes. A 780-nm diode laser is used to illuminate the optic nerve. The polarization state of the light emerging from the eye is then evaluated and correlated with RNFL thickness. Unlike CSLO, scanning laser polarimetry (SLP) can directly measure the thickness of the RNFL. GDx® is a common example of a scanning laser polarimeter. GDx® contains a normative database and statistical software package to allow comparison to age-matched normal subjects of the same ethnic origin. The advantages of this system are that images can be obtained without pupil dilation, and evaluation can be done in approximately 10 minutes. Current instruments have added enhanced and variable corneal compensation technology to account for corneal polarization.
   c. **Optical Coherence Tomography:** Optical coherence tomography (OCT) uses near-infrared light to provide direct cross-sectional measurement of the RNFL. The principles employed are similar to those used in B-mode ultrasound except light, not sound, is used to produce the 2-dimensional images. The light source can be directed into the eye through a conventional slit-lamp biomicroscope and focused onto the retina through a typical 78-diopter lens. This system requires dilation of the patient’s pupil. OCT® is an example of this technology.

2. Pulsatile Ocular Blood Flow
   a. The pulsatile variation in ocular pressure results from the flow of blood into the eye during cardiac systole. Pulsatile ocular blood flow can thus be detected by the continuous monitoring of intraocular pressure. The detected pressure pulse can then be converted into a volume measurement using the known relationship between ocular pressure and ocular volume. Pulsatile blood flow is primarily determined by the choroidal vessels, particularly relevant to patients with glaucoma, since the optic nerve is supplied in large part by choroidal circulation.
3. Doppler Ultrasonography
   a. Color Doppler imaging has also been investigated as a technique to measure the blood velocity in the retinal and choroidal arteries.

Regulatory Status

In 2012, The iExaminer™ (Welch Allyn) received marketing clearance from the U.S. Food and Drug Administration (FDA). The iExaminer consists of a hardware adapter and associated software (iPhone® App) to capture, store, send and retrieve images from the Welch Allyn PanOptic™ Ophthalmoscope using an iPhone®. FDA Product code: HKI

Policy

*This policy statement applies to clinical review performed for pre-service (Prior Approval, Precertification, Advanced Benefit Determination, etc.) and/or post-service claims.

Analysis of the optic nerve (retinal nerve fiber layer) in the diagnosis and evaluation of patients with glaucoma or glaucoma suspects may be considered medically necessary when using scanning laser ophthalmoscopy, scanning laser polarimetry, and optical coherence tomography.

The measurement of ocular blood flow, pulsatile ocular blood flow or blood flow velocity with Doppler ultrasonography is considered not medically necessary in the diagnosis and follow-up of patients with glaucoma.

Rationale

The use of various techniques of retinal nerve fiber layer (RNFL) analysis (confocal scanning laser ophthalmoscopy [CSLO], scanning laser polarimetry [SLP], and optical coherence tomography [OCT]) for the diagnosis and management of glaucoma was addressed by Technical Evaluation Center (TEC) Assessments in 2001 (1) and 2003. (2) The 2003 Assessment offered the following observations (2):

- A variety of techniques to evaluate the RNFL were considered, including CSLO, SLP, and OCT. All 3 devices use different principles to directly evaluate the RNFL. All 3 devices give multiple specific measurement of the RNFL that can be followed up over time to evaluate a rate of change in the RNFL. In theory, they are highly sensitive and can detect subtle changes to the RNFL earlier than standard qualitative evaluations. The major potential benefit of these technologies is that they can provide a quantitative objective evaluation in contrast with the subjective evaluation provided by other methods of diagnosing and monitoring primary open angle glaucoma (POAG).
- The Assessment evaluated whether adding RNFL analysis to other tests improves health outcomes. It is assumed that RNFL analysis would not influence decisions to begin treatment...
for suspected POAG when intraocular pressure is elevated or results of 2 of 3 conventional tests are positive. Conventional tests include ophthalmoscopic detection of atrophy of the optic nerve, visual field defect on perimetric testing, and increased intraocular pressure on tonometry. In patients without clear indications for topical medication, signs of optic nerve atrophy on RNFL analysis seen in advance of meeting other current diagnostic criteria for POAG may be used to begin early treatment. Using RNFL analysis to initiate early topical medication requires knowing how well RNFL results predict the development of visual loss. If the RNFL analysis is a poor predictor of future visual loss, its use could lead to errors in management, leading, for example, to overtreatment.

- RNFL analysis may also play a role in monitoring patients who have already begun treatment for POAG. Patients showing a failed response to treatment on RNFL analysis may be referred to take a different class of topical medication or to undergo laser trabeculoplasty.
- The best evidence would be direct evidence comparing outcomes of management guided by conventional tests with and without RNFL analysis.

The 2003 TEC Assessment (2) provided the following conclusions:

- No randomized trials compare the health outcomes of management guided by conventional tests alone to outcomes of management guided by conventional tests plus RNFL analysis in the detection or monitoring of POAG.
- The best available evidence on using RNFL analysis to predict visual loss comes from a study of scanning laser ophthalmoscopy (i.e., Heidelberg retinal tomography, HRT), in which 21 patients progressed from ocular hypertension to glaucoma (converters) and 164 patients did not progress (nonconverters). Of the 21 converters, 13 had abnormal HRT results, and in 11 of these the tests were positive before development of visual field defects (average lead time was 5.4 months). Of the 164 nonconverters, 47 had abnormal results. (3)
- The positive predictive value (PPV) of HRT, given the available data, was 22%. The frequency of true-positives and false-positives in the Kamal et al. study (3) may depend on the duration of follow-up completed in this study, which was a mean of at least 33 months. If the frequency of true- and false-positives stays the same with more adequate follow-up, the consequence would be overtreatment in 78% of patients with a positive HRT finding. Additional follow-up is needed to show whether some false-positives are late converters who become true-positives.
- Cross-sectional studies do not inform the prediction of future visual loss. These studies can reveal whether RNFL analysis can detect prevalent cases of glaucoma. RNFL analysis does not detect all prevalent cases; it is falsely negative in 14–36% of cases among recent cross-sectional studies using predetermined diagnostic criteria or blinded test interpretation.

Regarding pulsatile ocular blood flow or blood flow velocity (techniques not addressed by the TEC Assessment), there are similar deficiencies reported in the published literature. Specifically, no data from published clinical trials document how these devices should be incorporated into clinical practice and whether treatment decisions based on the use of these devices result in improved patient outcomes compared with the conventional methods of evaluation. Additional information is also needed to 1) document the association between blood flow and glaucoma; 2) determine the relevant
vessels for study considering the complex blood supply to the optic nerve; and 3) establish the range of normal values, particularly in relation to other factors such as blood pressure, heart rate, and compliance of the blood vessels. (4-8)

Evidence Subsequent to the 2003 TEC Assessment

The following is a summary of the relevant key literature to date:

In 2012, the Agency for Healthcare Research and Quality (AHRQ) published a comparative effectiveness review of screening for glaucoma. (9) Included in the review were randomized controlled trials (RCTs), quasi-randomized controlled trials, observational study designs including cohort and case control studies, and case series with more than 100 participants. The interventions evaluated included ophthalmoscopy, fundus photography/computerized imaging (OCT, retinal tomography, scanning laser polarimetry), pachymetry (corneal thickness measurement), perimetry, and tonometry. No evidence was identified that addressed whether an open angle glaucoma screening program led to a reduction in IOP, less visual impairment, reduction in visual field loss or optic nerve damage, or improvement in patient-reported outcomes. No evidence was identified regarding harms of a screening program. Over 100 studies were identified on the diagnostic accuracy of screening tests. However, due to the lack of a definitive diagnostic reference standard and heterogeneity, synthesis of results could not be completed.

1. Techniques to Evaluate the Optic Nerve/Retinal Nerve Fiber Layer

The Confocal Scanning Laser Ophthalmoscopy (CSLO) Ancillary Study, a subset of the Ocular Hypertension Treatment Study (OHTS), was designed to determine whether annual optic disc topographic measurements can accurately predict visual field loss. (10) The OHTS randomly assigned patients with elevated intraocular pressure to either topical hypotensive medication or observation. Baseline data reported from the CSLO Ancillary Study did not allow reaching conclusions about how well RNFL analysis measurements predict visual loss over time.

Follow-up of the CSLO Ancillary Study was reported in 2005. (11) Of 438 participants, 34% had abnormal CSLO values according to HRT criteria. The average interval between CSLO exams to POAG was 48.4 months (standard deviation [SD]: 25.2). Eyes not developing POAG were followed up a mean of 79.5 months (SD: 20.8). Sensitivity of CSLO for development of POAG using HRT criteria was 55.6% (95% confidence interval [CI]: 39.6 to 70.5%), specificity 68.2% (95% CI: 63.5 to 72.5%), and positive predictive value (PPV) 13.5% (95% CI: 8.9 to 20.0%). The investigators concluded that "[t]he current analysis did not directly determine whether the prediction model that includes baseline CSLO measurements is improved over the OHTS prediction model that includes baseline stereophotographic cup-disc ratio measurements…. Longer follow-up is required to evaluate the true predictive accuracy of CSLO measures."

At Manchester Royal Eye Hospital (UK), HRT and GDx systems were evaluated in cross-sectional (98 normal controls and 152 patients with POAG) and longitudinal studies (240 at risk of developing glaucoma due to high intraocular pressure or fellow eye with POAG and 75 with POAG). (12) With specificity set at 95%, sensitivities of the HRT and GDx in detecting POAG were 59% and 45%, respectively, in the cross-sectional study. In the longitudinal study, patients were evaluated biannually
over an average 3.5-year follow-up. Evidence of visual field defects developed in 72 of the at-risk group. Poor agreement was found between the HRT and GDx for development of visual field abnormalities. Although sensitivities might vary according to definitions for conversion to a visual field defect, among patients with baseline HRT and GDx abnormalities, sensitivities could be as low as 13% to 39%. The authors concluded that “on account of the fact that the HRT and GDx fail to detect a significant number of cases of conversion, they cannot provide a replacement for visual field examination.”

Longitudinal results have also been reported from the University of California, San Diego (UCSD) Diagnostic Innovations in Glaucoma Study (DIGS). (13, 14) In the first publication, eyes from 160 glaucoma suspects evaluated with SLP were followed up for 1.7 to 4.1 years. Visual field damage developed in 16 (10%) participants. Only relative risks (RRs) for visual field damage were reported as opposed to sensitivities, specificities, and predictive values. (13) From 12 SLP parameters and a 13th calculated from those parameters, 3 were significantly associated with the visual field outcome in multivariate analyses (models were incorrectly specified owing to the small number of outcomes). In a subsequent report, 114 glaucoma suspects were examined with OCT (one eye per patient). (14) Over a 4.2-year average follow-up, 23 (20%) developed changes consistent with glaucoma. While the RR of developing glaucomatous changes was increased with thinner RNFL results (1.5-fold per 10 micrometers), sensitivities and specificities demonstrating clinical utility were not reported.

Kalaboukhova et al. enrolled 55 patients with ocular hypertension (OHT) and POAG (34 and 25, respectively) who were followed up for a median of 47 months (range, 22–86 months). (15) HRT was performed at entry (1998–2002) and re-examined between 2001 and 2005. Based on optic disc photographs, eyes were classified as progressive or stable; 22 showed progression. From 25 parameters evaluated, 5 were accompanied by statistically significant areas under the receiver operating characteristic (ROC) curve. However, no adjustments were made for multiple comparisons; the sample was small and one of convenience.

A technology assessment issued by the AAO in 2007 reviewed 159 studies published between January 2003 and February 2006, evaluating optic nerve head and RNFL devices used to diagnose or detect glaucoma progression. (16) The assessment concluded, “The information obtained from imaging devices is useful in clinical practice when analyzed in conjunction with other relevant parameters that define glaucoma diagnosis and progression.”

Studies continue to report on use of these techniques in patients with glaucoma/glaucoma suspects. In addition, studies report correlation of changes in RNFL analysis and changes in visual fields. (17)

2. Pulsatile Ocular Blood Flow

Measurement of ocular blood flow has been studied as a technique for evaluating patients with glaucoma. One potential application is the early detection of normal tension glaucoma. (21) While reports of use have been longstanding, the report by Bafa et al. from 2001 (18) is one example, the clinical impact of this technique is not known. Reports have commented on the complexity of these parameters (19) and have also noted that these technologies are not commonly used in clinical settings. (20)
3. Blood Velocity Measured with Doppler Ultrasonography

In 2012, Calvo et al. reported the predictive value of retrobulbar blood flow velocities in a prospective series of 262 glaucoma suspects. (22) At baseline, all participants had normal visual field, increased IOP (mean of 23.56 mm Hg), and glaucomatous optic disc appearance. Blood flow velocities were measured by color Doppler imaging (CDI) during the baseline examination, and conversion to glaucoma was assessed at least yearly according to changes observed with confocal laser scanning. During the 48-month follow-up period, there were 36 converters (13.7%) and 226 non-converters. Twenty of the converters (55.5%) also showed visual field worsening (moderate agreement, kappa=0.38). Mean end-diastolic and mean velocity in the ophthalmic artery were significantly reduced at baseline in subjects who converted to glaucoma compared to subjects who did not convert. Post-hoc subgroup analysis comparing patients with resistivity lower than 0.75 to those with resistivity greater than 0.75 revealed statistically significant differences in those not converting to glaucoma (survival of 93.9% vs. 81.7%, respectively). The clinical significant of this difference is unclear.

A 2011 publication reported on color Doppler imaging (CDI) in normal and glaucomatous eyes. (23) Using data from reported studies, a weighted mean was derived for the peak systolic velocity, end diastolic velocity and Pourcelot's resistive index in the ophthalmic, central retinal and posterior ciliary arteries. Data from 3,061 glaucoma patients and 1,072 controls were included. The mean values for glaucomatous eyes were within 1 SD of the values for controls for most CDI parameters.

Methodologic differences created inter-study variance in CDI values, complicating the construction of a normative database and limiting its utility. The authors noted that because the mean values for glaucomatous and normal eyes have overlapping ranges, caution should be used when classifying glaucoma status based on a single CDI measurement.

Resch and colleagues reported a cross-sectional study of optic disc morphology and ocular perfusion parameters in 103 patients with primary open angle glaucoma (POAG) in 2011. (24) Choroidal and optic nerve head blood flow was assessed using laser Doppler flowmetry, retinal blood velocity was measured with laser Doppler velocimetry, and retinal vessel diameters were measured with a Retinal Vessel Analyzer. Choroidal blood flow was not significantly associated with measures of glaucomatous damage or with morphologic parameters of the optic nerve head. Reduced retinal vessel diameters were slightly correlated with the degree of glaucomatous damage. Multiregression analysis showed optic nerve head blood flow to be most strongly associated with most measures of structural nerve head damage (e.g., r=0.28 for RNFL) and visual field loss. As indicated in the TEC Assessment, cross-sectional studies cannot determine whether changes in blood flow precede or are secondary to changes in the optic nerve head. Longitudinal studies are needed to evaluate if changes in blood flow are predictive of future visual loss.

Practice Guidelines and Position Statements

The American Academy of Ophthalmology (AAO) 2010 POAG Suspect and POAG Preferred Practice Patterns recommend evaluating the optic nerve and retinal nerve fiber layer. (25) The documents state that “Stereoscopic disc photographs and computerized images of the nerve are distinctly
different methods for optic nerve documentation and analysis. Each is complementary with regard to the information they provide the clinician who must manage the patient.” The guidelines describe 3 types of computer-based imaging devices that are currently available for glaucoma and are similar in their ability to distinguish glaucoma from controls: confocal scanning laser ophthalmoscopy, optical coherence tomography, and scanning laser polarimetry. “When examined for the ability of these devices to detect glaucoma progression, studies have shown a relative lack of concordance between the structural (the imaging devices) and functional (visual field) tests. Taken together, computer-based imaging devices for glaucoma provide useful, quantitative information for the clinician when analyzed in conjunction with other relevant clinical parameters.”

The American Optometric Association issued a 2010 clinical guideline on the care of the patient with open angle glaucoma. (26) The guideline list states that follow-up examinations for the evaluation of POAG may include but is not limited to biomicroscopy, tonometry, gonioscopy, and optic nerve assessment.

U.S. Preventive Services Task Force Recommendations

Not applicable.

Summary

Numerous articles describe findings from patients with known and suspected glaucoma using scanning laser ophthalmoscopy, scanning laser polarimetry, and optical coherence tomography. These studies report that abnormalities may be detected on these examinations before functional changes are noted. (27) The literature, specialty society guidelines, and clinical input indicate that optic nerve analysis using CSLO, SLP, and OCT has become an additional test that may be used in the diagnosis and management of patients with glaucoma and those who are glaucoma suspects. These results are often considered along with other findings to make diagnostic and therapeutic decisions about glaucoma care. Thus, this testing may be considered medically necessary.

Techniques to measures ocular blood flow or ocular blood velocity are used in evaluating various glaucoma treatments. The data for these techniques remain limited. Literature reviews have not identified studies that demonstrate the clinical utility for use of pulsatile ocular blood flow or blood flow velocity in patients with glaucoma. Some publications have described their use in studies comparing medication regimens in glaucoma. Others have suggested that these parameters may be helpful in understanding the variability in visual field changes in patients with glaucoma, i.e., this may help explain why patients with similar levels of intraocular pressure may develop markedly different visual impairments. However, data on use of ocular blood flow, pulsatile ocular blood flow, and/or blood flow velocity are currently lacking, and their relationship to clinical outcomes is not known. Therefore, their use remains not medically necessary.

Medicare National Coverage

No national coverage decisions were identified.
